Abstract. This study investigated drought and flooding changes in West Africa between 1983–2012 and projected near future (2025–2054) periods. The datasets used are the CHIRTS and CHIRPS-2 for observed reanalysis and five (05) models of ISIMIP2b for Shared Socio-economic Pathways (SSP1.2.6 and SSP5.8.5). Extremely and very wet days total precipitation (R95pTOT; R99pTOT) and Standardized Precipitation Evapotranspiration Index (SPEI) were employed to investigate floods and drought spatial distribution using Sen Slope trend analysis method. The results showed that there is a variability in the spatial distribution of extreme indices with an upward and downward trend of dry and wet rainfall periods in West Africa in both historical and projected periods. This observation suggests that the study area is faced with rainfall variability marked by extreme events. A further examination on the spatial and temporal distribution of flood occurrence showed that more flood events were observed in the Gulf of Guinea and Savannah countries, followed by an increase in uniform spatial distribution and moderate wet days both under SSP1.2.6, and SSP 5.8.5. In addition, result showed that an upward trend in wet periods can cause the occurrence of extreme events associated with floods in the context of global warming. However, with these scenarios negative changes are not excluded in the East, the Sahel and some western part of the Gulf of Guinea in the study area for the SSP5.8.5 scenario. Thus, the results revealed that the spatio-temporal variability of extreme rainfall can have repercussions on the hydrological functioning of watersheds, water availability and water-dependent activities.

Keywords. Flood; drought; extreme precipitation; SPEI; global warming; West Africa

1 Introduction

In recent decades, West Africa has been faced with a high frequency and intensity of extreme hydro-meteorological events which are mostly detrimental to socio-economic and environmental issues (Quenum et al., 2019; Ajayi et al., 2020). Thus, with the effects of global warming, precipitation regimes are not only affected, but also an uneven distribution of precipitation is observed with repercussions on the hydrodynamic functioning of watersheds and the quality of water resources within the ecosystems (Quenum et al., 2019). The Inter-Governmental Panel on Climate Change (IPCC) predicts changes in temperature and precipitation regimes with a high degree of confidence in the increase in the frequency of extreme events (Pedersen et al., 2022). This frequency is linked to the increase in the intensity and duration of storms, cold or heat waves, the increase in the extent of regions affected by drought and unexpected floods accompanied by uneven consequences distributed for many regions. According to Obahoundjè et al. (2017), the rainfall recession can reduce the availability of water resources with exacerbation on agricultural land, industry, energy, food security and river flow regimes. As for the occurrence of extreme rainfall, it can cause the destruction of lives and properties of communities, most of which are already vulnerable to extreme weather and climate conditions with threats of terrorism (Odoulami et al., 2019). Faced with this situation, the analysis of the spatio-temporal distribution of rainfall as well as that of these trends arouse the curiosity of this study not only to contribute to the improvement and integrated management of water resources but also for policy formulation, taking into account the impact of climate change on socio-economic and environmental developmental programs with a view to integrating it into the Sustainable Development Goals (SDGs). The analysis of various characteristics and trends of precipitation is an essential task to improve the utilization of water resources. To do this, several works have frequently used trend analysis in the context of rainfall or even hydrological variability based on approaches such as linear regression, Sen slope, Spearman's rho and trend tests by Mann-Kendall (Quenum et al., 2019). However, this study conducted statistical analyses of precipitation data using the Sen's slope that is basically applied to identify the magnitude of trend in a data series which are not serially auto-correlated (Şen, 2015).

The study therefore seek to investigate the extreme events of drought and flooding inherent to rainfall in coastal countries in West Africa in the context of global warming.

1.1 The study area

The study area (Fig. 1) is located between latitudes 0–20° N and longitudes 20° E–20° W which covers the Sahel, the

Table 1. Type of the scenarios.

Types of Scenarios	Description
SSP1-2.6	More gradual decline in emissions than RCP2.6 and a higher starting point
SSP2-4.5	Higher starting point and slightly slower decline than RCP4.5
SSP4-6.0	Quite different from RCP6.0, with CO ₂ emissions peaking and declining
SSP3-7.0	Middle of the range of baseline results produced by energy system models.
SSP5-8.5	Substantially higher CO ₂ emissions than RCP8.5

Sudano-Sahelian and the Guinea coast regions. The study focused much more on this last region with specific analyses on the coastal countries (Senegal, Côte d'Ivoire, Benin, Togo and Nigeria) which have watersheds with hydrological potential for energy and agricultural purposes.

2 Data sources and methods

2.1 Data sources

For this study we used the daily observed reanalysis covering (1983–2012) of CHIRTS (T_{\min} and T_{\max}) and CHIRPS-2 (Rainfall) for $0.05^\circ \times 0.05^\circ$ resolution to evaluate the accuracy of the climate models (<https://data.chc.ucsb.edu/products/CHIRPS-2.0/>, last access: 7 September 2023) CHIRTS and CHIRPS-2 data have been validated with observation over West Africa by previous studies (Atiah et al., 2020; Dembélé et al., 2016). The ensemble mean of the five models of ISIMIP2b (GFDL, IPSL, MPI, MRI, UKESM1, daily $0.5^\circ \times 0.5^\circ$) of (pr, tasmin, tasmax) over the historical period spanning 1983 to 2012 and near future 2025–2054 with the scenarios SSP 1.2.6 and SSP 5.8.5 were merged to analyse drought and flooding areas in coastal countries of West Africa (Table 1) <https://www.isimip.org/gettingstarted/isimip2b-bias-adjustment/> (last access: 7 September 2023).

We used minimum and maximum temperature to compute the Potential Evapotranspiration (PET) in the study area.

2.2 Methods

2.2.1 Characterization of flood events

For the characterization of areas or land prone to drought or flooding in the coastal countries of West Africa in the context of global warming, certain indices were developed by the Ex-

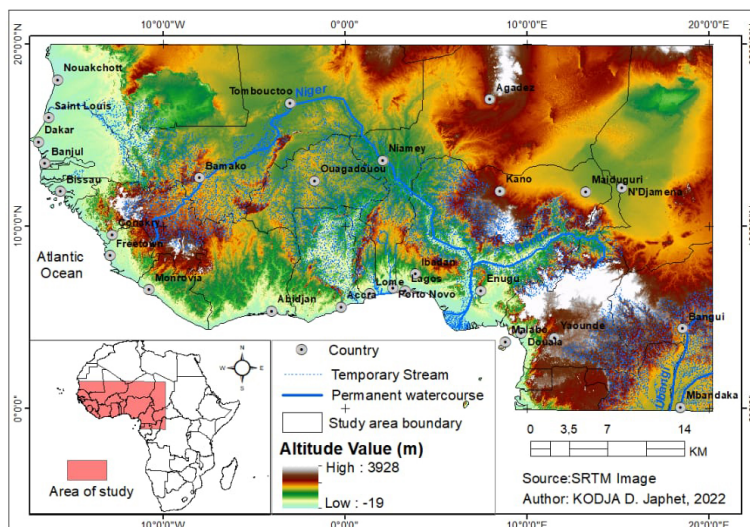

Figure 1. Geographical location of the study area.

pert Team on Climate Change Detection Indices (ETCCDI) were employed. Detailed descriptions of these indices are available on the ETCCDI website (<http://ccma.seos.uvic.ca/ETCCDMI/software.shtml>, last access: 7 September 2023). In the present study, two (02) indices were calculated and they are based on the extreme rainfall characteristic of floods.

- *R95pTOT*. Annual total PRCP when $RR > 95p$. Let RR_{wj} be the daily precipitation amount on a wet day w ($RR \geq 1.0$ mm) in period I and let RR_{wn95} be the 95th percentile of precipitation on wet days. If W represents the number of wet days in the period. $R95pTOT$ were calculated by Eq. (1):

$$R95_{pj} = \sum_{w=1}^w RR_{wj} \text{ with } RR_{wj} > RR_{wn95} \quad (1)$$

- *R99pTOT*. Annual total PRCP when $RR > 99p$: Let RR_{wj} be the daily precipitation amount on a wet day w ($RR \geq 1.0$ mm) in period i and let RR_{wn99} be the 99th percentile of precipitation on wet days. If W represents the number of wet days in the period. $R99pTOT$ were calculated by Eq. (2):

$$R99_{pj} = \sum_{w=1}^w RR_{wj} \text{ with } RR_{wj} > RR_{wn99} \quad (2)$$

2.2.2 Standardized Precipitation and Evapotranspiration Index (SPEI)

The normalized precipitation evapotranspiration index (SPEI) was highlighted in 2010 and has been the subject of several studies in climatology, hydrology, water availability and in research relating to agrarian systems (N’guessan Bi

Table 2. Classification of SPEI values.

Periods	Indicators	SPEI Values
Wet periods	Extremely wet	$SPEI \geq 2$
	Severalty/very wet	$1.5 \leq SPEI < 1.99$
	Moderately wet	$1 \leq SPEI < 1.49$
Near-Normal periods	Near-Normal	$-0.99 < SPEI < 0.99$
Drought periods	Moderately dry	$-1.49 < SPEI \leq -1$
	Severalty/very dry	$-1.99 < SPEI \leq -1.5$
	Extremely dry	$SPEI \leq -2$

Source: Adapted from Vicente-Serrano et al. (2010).

et al., 2020). The normalized precipitation evapotranspiration index (SPEI) focus on the difference between precipitation and potential evaporation instead of just precipitation (Vicente-Serrano et al., 2010). Thus, given its specificity in measuring the severity of drought, analyzed drought variability and also of extreme wetness (Allen et al., 2011), it was adopted in this research. The normalized precipitation evapotranspiration index were calculated for 1, 3, 6, 9 and 12 months on each grid point for each dataset (Quenum et al., 2019). However for this study, the results presented are those of the SPEI generated over 12 months because the latter provide a representation of long-term precipitation patterns such as those calculated over 12 months and contribute to the detection of hydrological impacts (OMM and GWP, 2016). The calculation method used in this research is presented in Table 2.

The computation of potential evapotranspiration is used to calculate the normalized Precipitation-Evapotranspiration Index (SPEI). For that, Thornthwaite equation was used in this research.

Figure 2. Trends of the slope in the precipitation on very and extremely wet period during 1983–2012.

2.2.3 Method of trend analysis

Trend analysis of rainfall time series includes determination of increasing and decreasing trend and magnitude of trend and its statistical significance” (Quenum et al., 2019). Then the Sen Slope trend was employed for this research. In addition these indicators were calculated on historical (1983–2012) and near future periods (2025–2054) of precipitation in West Africa.

3 Results and discussion

3.1 Spatial trend analysis of precipitation on very wet by R95pTOT and extremely wet R99pTOT under historical period (1983–2012)

The spatial trend of the extremely wet period under 1983–2012 (Fig. 2), reveals on the one part that the very wet period (R95pTOT) trend increase (between 0 to 0.5) over the entire West Africa domain characterized by a positive slope. It is important to note that this increase is slightly small in Southern and concern Benin, Togo, Ghana, Ivory Coast during the historical periods. This is also true in Sahel countries.

As for the trend of extremely wet (R99pTOT) period, a slight increase was observed (between 0 to 1) over the entire West Africa domain characterized by a positive slope. For this result, it is clear that there will be a decreasing trend of R99pTOT along the Guinea Coast (North Benin, Togo and Ghana). A similar trend was also observed in other countries located in the Sahara and Sahel such as Burkina Faso and Mali as well as Northern Cameroon and the lac Tchad.

3.2 Spatial trend analysis of precipitation on very wet by R95pTOT and extremely wet R99pTOT near future period (2025–2054) with scenario SSP 1.2.6 and SSP 5.8.5

Trend in very wet period characterize by R95pTOT (Fig. 3) shows a slight decrease and increase trend during the SSP 1.2.6 scenario in the near future while the results reveals a clear increasing trend over the entire West Africa domain under SSP 5.8.5 scenario characterized by a positive slope.

The analysis of the results by R99pTOT (Fig. 4) shows a slight decrease trend during the SSP1.2.6 scenario in the near future while we noted a clear increasing trend over the entire

Figure 3. Trend of Slope on very wet period in near future period (2025–2054) with scenario SSP 1.2.6 and SSP 5.8.5.

Figure 4. Trend of Slope of the Scenarios SSP 1.2.6 and SSP 5.8.5 of wet period from SPEI for 12 months on 2025–2054.

West Africa, basically in the gulf of Guinea under SSP 5.8.5 scenario characterized by a positive slope (Fig. 4).

3.3 Analysis of trend in the wet and drought period with SPEI for 12 months in the historical period (1983–2012)

From near normal to extremely wet (Fig. 5), the spatial analysis of trend by SPEI under 12 months, show a slight decrease (between 0 to -2) and an increase (between 0 to 2) trend during the historical which varies from one country to another. Such a situation can contribute to the occurrence of floods.

Concerning the characterization of drought (Fig 6), it was observed that from moderate to extremely dry, the spatial analysis of trend by SPEI shows a slight increase (between 0 to 1) and decrease (between 0 to -2) trend during the historical area; which suggests that there is an upward trend of wet rain events reported on the analysis of Fig. 3.

This situation described above may have repercussions both on water-dependent activities and on the hydrological and hydroelectric dynamics of the West African watersheds.

The results show that from normal to extremely wet, the spatial analysis of trend by SPEI show a slight decrease (between 0 to -2) and increase (between 0 to 2) which varies from one country to another in near future (2025–2054) under the SSP 1.2.6 (Fig. 7).

According to the analysis of Fig. 8, it should be noted that the same scenario under SSP 1.2.6 was observed but the wet period under SSP 5.8.5 will decrease slightly more than the SSP 1.2.6 scenario.

Based on this result, we inferred that the data from the SSP 1.2.6 scenarios are less pessimistic than those of SSP 5.8.5 and can be used to characterize wet rainfall events.

Figure 5. Trend of the slope of historical wet from SPEI for 12 months under 1983–2012.

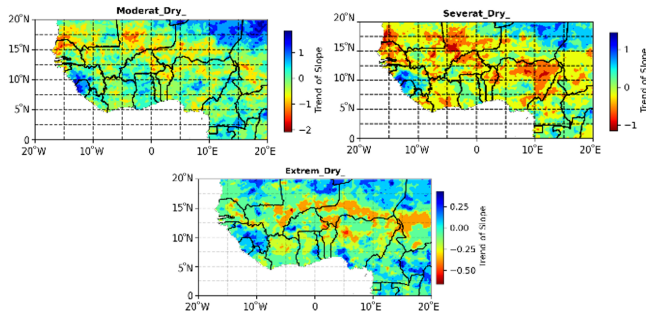

Figure 6. Trend of the slope of historical drought from SPEI for 12 months under 1983–2012.

During the near future period (2025–2054) with scenario SSP 1.2.6, the results (Fig. 9), depict moderate to extremely dry, while the spatial trend by the SPEI show a slight increase of dry period in costal country in the Gulf of Guinea and significance increase in the Sahel under the SSP 1.2.6.

This situation with SSP 1.2.6 scenario in the Gulf of Guinea may be due to the influence of other physical factors such as oceanic effects that contributed to rainfall and the regulation of global warming.

The results of Fig. 10, revealed the same situation as scenario SSP 1.2.6. However, the drought with SSP 5.8.5 will be slightly more severe than the 1.2.6 scenario that was characterized by the drought period. We opined that the data of the SSP 5.8.5 scenario are more pessimistic than those of the SSP 1.2.6 scenario in terms of global warming.

4 Conclusions

The study confirmed that there is variability in the spatial distribution of rainfall indices with an upward and downward trend of dry and wet periods in the study area.

This situation is much more remarkable in the countries of the Gulf of Guinea and can however cause extreme rainfall events associated with floods or dry spells and consequently repercussions on water-dependent activities and the hydrological dynamics of rivers. Considering the data series studied, the upward trends in rainfall confirmed the return period

Figure 7. Trend of the in the wet period from SPEI for 12 months in near future period (2025–2054) with scenario SSP 1.2.6.

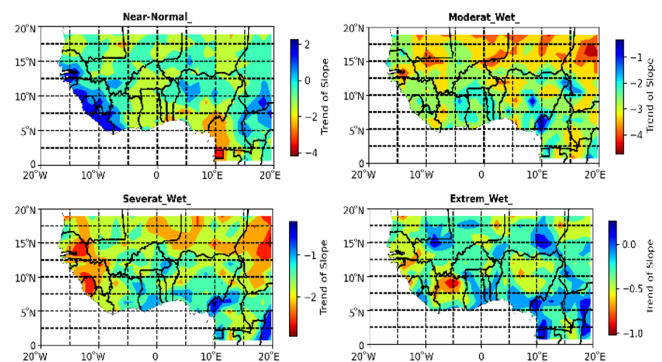

Figure 8. Trend of the in the wet period with SPEI for 12 months in near future period (2025–2054) with scenario SSP 1.2.6.

Figure 9. Trend of the in the drought period with SPEI for 12 months in near future period (2025–2054) with scenario SSP 1.2.6.

of rainfall reported in many studies over West African countries. However, the upward trend is weak. In conclusion, the countries of the Gulf of Guinea and the Sahelian border to the north of the study area are the wettest. In addition, the upward or downward trend varies from one scenario to another. The data analysis of the different scenarios SSP 1.2.6 and 5.8.5 deserve to be deepened in future studies.
